Furthermore, all non-paraventricular and hypothalamic lesions were detected on DWI and ADC-based lesion detection was almost equally sensitive compared to FLAIR sequences. These additional lesions found on DWI are usually missed by visual assessment of FLAIR images. Therefore, during clinical practice FLAIR sequences should be carefully performed to rule out underlying brain parenchymal pathologies that significantly alter the perception of brain tumors. In our study, we found few lesions not detected on T2-FLAIR sequences. We suspect that this observation is due to high lesion contrast in FLAIR images. This might be the reason why all lesions shown were visible in FLAIR sequences as well. Regarding the false positive detections of T2-FLAIR, a normal anatomical finding, i.e. cervical vertebra IV and multiple supra- and infraependymal cysts, was considered the main cause of false positives on T2-FLAIR. Interestingly, these observations could also be identified on DWI, where their appearances are matched by the edema in the surrounding brain parenchyma. In fact, this finding can be seen as well in cases of high-grade glioma. MRI does not differentiate between reactive and inflammatory processes from malignancy. Therefore, in clinical practice, it is important to perform FLAIR sequences as T2-weighted sequences alone can be misinterpreted as malignant lesions
